EXECUTIVE SUMMARY

This report summarizes the methods and sources of information used to prepare the Seismic Hazard Zone Map for the Alameda County portion of the Oakland East 7.5-Minute Quadrangle. The map displays the boundaries of zones of required investigation for liquefaction and earthquake-induced landslides over an area of approximately 40 square miles at a scale of 1 inch = 2,000 feet.

Within the Oakland East Quadrangle, the cities of Oakland and Berkeley are contiguous and occupy flatlands along the margin of San Francisco Bay and steep hilly areas in the Oakland-Berkeley hills. Piedmont occupies a low hilly area east of Oakland. Alameda occupies an island that is separated from Oakland by a tidal channel. The area encompassed by these cities covers approximately one-half of the southern and western sides of the quadrangle. The remainder of the quadrangle consists of Contra Costa County land, Redwood Park and Anthony Chabot Regional Park, which have not been evaluated for seismic hazards. The flatland areas in Oakland, Berkeley and Alameda are heavily developed for residential and commercial use. Many of the hilly areas in Oakland, Berkeley and Piedmont also have been developed for residential use. Elevations range from sea level to more than 1,500 feet along the crest of the Oakland-Berkeley Hills. Numerous creeks flow from the hills across the alluvial plain to San Francisco.

The map is prepared by employing geographic information system (GIS) technology, which allows the manipulation of three-dimensional data. Information considered includes topography, surface and subsurface geology, borehole data, historical ground-water levels, existing landslide features, slope gradient, rock-strength measurements, geologic structure, and probabilistic earthquake shaking estimates. The shaking inputs are based upon probabilistic seismic hazard maps that depict peak ground acceleration, mode magnitude, and mode distance with a 10 percent probability of exceedance in 50 years.

In the Oakland East Quadrangle the liquefaction zone includes all of Alameda, much of Oakland west of Interstate Highway 580 and several of the larger creek beds. Landslides are abundant and widespread in the weak rocks of the hills. Approximately 20 percent of the Alameda County land area in the Oakland East Quadrangle lies within the earthquake-induced landslide hazard zone.
How to view or obtain the map

Seismic Hazard Zone Maps, Seismic Hazard Zone Reports and additional information on seismic hazard zone mapping in California are available on the California Geological Survey's Internet page: http://www.conservation.ca.gov/CGS/index.htm

Paper copies of Official Seismic Hazard Zone Maps, released by CGS, which depict zones of required investigation for liquefaction and/or earthquake-induced landslides, are available for purchase from:

    BPS Reprographic Services
    945 Bryant Street
    San Francisco, California 94105
    (415) 512-6550

Seismic Hazard Zone Reports (SHZR) summarize the development of the hazard zone map for each area and contain background documentation for use by site investigators and local government reviewers. These reports are available for reference at CGS offices in Sacramento, San Francisco, and Los Angeles. **NOTE: The reports are not available through BPS Reprographic Services.**
INTRODUCTION

The Seismic Hazards Mapping Act (the Act) of 1990 (Public Resources Code, Chapter 7.8, Division 2) directs the California Department of Conservation (DOC), Division of Mines and Geology (DMG) [now called California Geological Survey (CGS)] to delineate seismic hazard zones. The purpose of the Act is to reduce the threat to public health and safety and to minimize the loss of life and property by identifying and mitigating seismic hazards. Cities, counties, and state agencies are directed to use the seismic hazard zone maps in their land-use planning and permitting processes. They must withhold development permits for a site within a zone until the geologic and soil conditions of the project site are investigated and appropriate mitigation measures, if any, are incorporated into development plans. The Act also requires sellers (and their agents) of real property within a mapped hazard zone to disclose at the time of sale that the property lies within such a zone. Evaluation and mitigation of seismic hazards are to be conducted under guidelines adopted by the California State Mining and Geology Board (SMGB) (DOC, 1997). The text of this report is on the Internet at http://gmw.consrv.ca.gov/shmp/webdocs/sp117.pdf

The Act also directs SMGB to appoint and consult with the Seismic Hazards Mapping Act Advisory Committee (SHMAAC) in developing criteria for the preparation of the seismic hazard zone maps. SHMAAC consists of geologists, seismologists, civil and structural engineers, representatives of city and county governments, the state insurance commissioner and the insurance industry. In 1991 SMGB adopted initial criteria for delineating seismic hazard zones to promote uniform and effective statewide implementation of the Act. These initial criteria provide detailed standards for mapping regional liquefaction hazards. They also directed CGS to develop a set of probabilistic seismic maps for California and to research methods that might be appropriate for mapping earthquake-induced landslide hazards.

In 1996, working groups established by SHMAAC reviewed the prototype maps and the techniques used to create them. The reviews resulted in recommendations that 1) the process for zoning liquefaction hazards remain unchanged and 2) earthquake-induced landslide zones be delineated using a modified Newmark analysis.

This Seismic Hazard Zone Report summarizes the development of the hazard zone map. The process of zoning for liquefaction uses a combination of Quaternary geologic mapping, historical ground-water information, and subsurface geotechnical data. The process for zoning earthquake-induced landslides incorporates earthquake loading, existing landslide features, slope gradient, rock strength, and geologic structure. Probabilistic seismic hazard maps, which are the underpinning for delineating seismic hazard zones, have been prepared for peak ground acceleration, mode magnitude, and mode distance with a 10 percent probability of exceedance in 50 years (Petersen and others, 1996) in accordance with the mapping criteria.
This report summarizes seismic hazard zone mapping for potentially liquefiable soils and earthquake-induced landslides in the Oakland East 7.5-Minute Quadrangle.
SECTION 1
LIQUEFACTION EVALUATION REPORT

Liquefaction Zones in the
Oakland East 7.5-Minute Quadrangle,
Alameda County, California

By

Jacqueline D. J. Bott, Wayne D. Haydon, and Keith L. Knudsen

California Department of Conservation
California Geological Survey

PURPOSE
The Seismic Hazards Mapping Act (the Act) of 1990 (Public Resources Code, Chapter 7.8, Division 2) directs the California Department of Conservation (DOC), Division of Mines and Geology (DMG) [now called California Geological Survey (CGS)] to delineate Seismic Hazard Zones. The purpose of the Act is to reduce the threat to public health and safety and to minimize the loss of life and property by identifying and mitigating seismic hazards. Cities, counties, and state agencies are directed to use seismic hazard zone maps developed by CGS in their land-use planning and permitting processes. The Act requires that site-specific geotechnical investigations be performed prior to permitting most urban development projects within seismic hazard zones. Evaluation and mitigation of seismic hazards are to be conducted under guidelines adopted by the California State Mining and Geology Board (SMGB) (DOC, 1997). The text of this report is on the Internet at http://gmw.consrv.ca.gov/shmp/webdocs/sp117.pdf

Seismic Hazard Zone maps for the cities of Oakland and Piedmont were released as official maps in March of 2000 (DOC, 1999). The release of this new map and report includes the remaining areas within Alameda County in the Oakland East Quadrangle. The liquefaction zones of required investigation have been modified slightly (Witter, unpublished), primarily because of the availability of new, more detailed Quaternary
geologic mapping, new shallow ground-water data and a revised method of mapping the margins of the liquefaction zone of required investigation.

Following the release of DMG Special Publication 117 (DOC, 1997), agencies in the Los Angeles metropolitan region sought more definitive guidance in the review of geotechnical investigations addressing liquefaction hazards. The agencies made their request through the Geotechnical Engineering Group of the Los Angeles Section of the American Society of Civil Engineers (ASCE). This group convened an implementation committee under the auspices of the Southern California Earthquake Center (SCEC). The committee, which consisted of practicing geotechnical engineers and engineering geologists, released an overview of the practice of liquefaction analysis, evaluation, and mitigation techniques (SCEC, 1999). This text is also on the Internet at: http://www.scec.org/

This section of the evaluation report summarizes seismic hazard zone mapping for potentially liquefiable soils in the Oakland East 7.5-Minute Quadrangle. Section 2 (addressing earthquake-induced landslides) and Section 3 (addressing potential ground shaking), complete the report, which is one of a series that summarizes production of similar seismic hazard zone maps within the state (Smith, 1996). Additional information on seismic hazards zone mapping in California is on CGS’s Internet web page: http://www.conservation.ca.gov/CGS/index.htm

BACKGROUND

Liquefaction-induced ground failure historically has been a major cause of earthquake damage in northern California. During the 1989 Loma Prieta and 1906 San Francisco earthquakes, significant damage to roads, utility pipelines, buildings, and other structures in the San Francisco Bay Area was caused by liquefaction-induced ground displacement.

Localities most susceptible to liquefaction-induced damage are underlain by loose, water-saturated, granular sediment within 40 feet of the ground surface. These geological and ground-water conditions are widespread in the San Francisco Bay Area, most notably in alluviated valley floodplains and around the margin of the bay. In addition, the potential for strong earthquake ground shaking is high because of the many nearby active faults. The combination of these factors constitutes a significant seismic hazard in the San Francisco Bay Area, including areas in the Oakland East Quadrangle.

METHODS SUMMARY

Characterization of liquefaction hazard presented in this report requires preparation of maps that delineate areas underlain by potentially liquefiable sediment. The following were collected or generated for this evaluation:

- Existing geologic maps were used to provide an accurate representation of the spatial distribution of Quaternary deposits in the study area. Geologic units that generally
are susceptible to liquefaction include late Quaternary alluvial and fluvial
sedimentary deposits and non-engineered artificial fill

- Construction of shallow ground-water maps showing the historically highest known
ground-water levels

- Quantitative analysis of geotechnical data to evaluate liquefaction potential of
deposits

- Information on potential ground shaking intensity based on CGS probabilistic shaking
maps

The data collected for this evaluation were processed into a series of geographic
information system (GIS) layers using commercially available software. The liquefaction
zone map was derived from a synthesis of these data and according to criteria adopted by
the SMGB (DOC, 2000).

SCOPE AND LIMITATIONS

Evaluation for potentially liquefiable soils generally is confined to areas covered by
Quaternary (less than about 1.6 million years) sedimentary deposits. Such areas within
the Oakland East Quadrangle consist mainly of gently sloping alluvial fans and areas
bordering larger streams, low-lying shoreline regions, alluviated valleys, floodplains, and
canyons. CGS’s liquefaction hazard evaluations are based on information on earthquake
ground shaking, surface and subsurface lithology, geotechnical soil properties, and
ground-water depth, which is gathered from various sources. Although selection of data
used in this evaluation was rigorous, the quality of the data used varies. The State of
California and the Department of Conservation make no representations or warranties
regarding the accuracy of the data obtained from outside sources.

Liquefaction zone maps are intended to prompt more detailed, site-specific geotechnical
investigations, as required by the Act. As such, liquefaction zone maps identify areas
where the potential for liquefaction is relatively high. They do not predict the amount or
direction of liquefaction-related ground displacements, or the amount of damage to
facilities that may result from liquefaction. Factors that control liquefaction-induced
ground failure are the extent, depth, density, and thickness of liquefiable materials, depth
to ground water, rate of drainage, slope gradient, proximity to free faces, and intensity
and duration of ground shaking. These factors must be evaluated on a site-specific basis
to assess the potential for ground failure at any given project site.

Information developed in the study is presented in two parts: physiographic, geologic,
and hydrologic conditions in PART I, and liquefaction and zoning evaluations in PART
II.
PART I

PHYSIOGRAPHY

Study Area Location and Physiography

The Oakland East 7.5-Minute Quadrangle covers approximately 60 square miles in Alameda and Contra Costa counties east of San Francisco Bay. The boundary between Alameda and Contra Costa counties trends northwesterly through the northeastern portion of the quadrangle, approximately coinciding with the crest of the Berkeley Hills. The 40 percent (approximately 25 square miles) of the quadrangle within Contra Costa County or within regional park land including: Joaquin Miller, Redwood, and Chabot parks is outside of the area evaluated for zoning.

Parts of the cities of Oakland, Piedmont, Berkeley, and Alameda are within the western half of the quadrangle. Oakland and Berkeley are contiguous and occupy flatlands along the margin of the bay as well as steep hilly areas in the Oakland-Berkeley hills. Piedmont is within a low hilly area on the east side of Oakland. Alameda is on an island in San Francisco Bay that is separated from Oakland by a tidal canal.

The flatland areas in Oakland, Berkeley, and Alameda are heavily developed for residential and commercial use. Most of the hilly areas in Oakland, Berkeley and Piedmont also have been developed for residential use. Hillside areas are accessed by a system of steep, winding roads.

Elevations in the map area range from sea level along the shore of San Francisco Bay to more than 1,500 feet along the crest of the Oakland-Berkeley hills. The Berkeley Hills are drained by numerous creeks, which extend primarily westward across the alluvial plain to San Francisco Bay. Some of the creeks in the quadrangle include Palo Seco, Peralta, Sausal, Shephard, Temescal and Arroyo Viejo.

Major highways include northwest-trending Interstate 880 along the shoreline of San Francisco Bay, Interstate 580 through the central part of Oakland, State Highway 13 between Berkeley and Oakland and northeast trending State Highway 24 that from Berkeley and Oakland through the Caldecott Tunnel to Contra Costa County. A network of secondary roads links these major highways. Bay Area Rapid Transit (BART) is located slightly east and subparallel to Interstate 880.

GEOLOGY

Bedrock and Surficial Geology

Geologic units that generally are susceptible to liquefaction include late Quaternary alluvial and fluvial sedimentary deposits and artificial fill. To evaluate the areal and vertical distribution of shallow Quaternary deposits and to provide information on subsurface geologic, lithologic and engineering properties of the units in the Oakland
East Quadrangle, digital maps were obtained from the U.S. Geological Survey. These include unpublished Quaternary mapping by Robert C. Witter (unpublished) and a published map of part of Alameda County (Graymer, 2000). These GIS maps were combined, with minor modifications along the bedrock/Quaternary contact, to form a single, 1:24,000-scale geologic map of the Oakland East Quadrangle. The distribution of Quaternary deposits on this map (summarized on Plate 1.1) was used in combination with other data, discussed below, to evaluate liquefaction susceptibility and develop the Seismic Hazard Zone Map.

Other geologic maps and reports were reviewed, including Lawson (1908), Trask and Rolston (1951), Louderback (1951), Radbruch (1959), Mitchell (1963), Treasher (1963), Radbruch (1969), Atwater and others (1977), Helley and others (1979), Rogers and Figuers (1992), Sloan (1992), Lienkamper (1992), Graymer and others (1996), Helley and Graymer (1997), Figuers (1998), Knudsen and others (2000b), and Geomatrix Consultants, Inc. (2000). Limited field reconnaissance was conducted to confirm the location of geologic contacts, map recently modified ground surfaces, observe properties of near-surface deposits, and characterize the surface expression of individual geologic units.

Witter (unpublished) mapped 14 Quaternary map units in the Oakland East Quadrangle. The Quaternary geologic mapping methods used by Witter (unpublished) in his mapping of the Oakland East Quadrangle are the same as those described by Knudsen and others (2000b). The methods consist of interpretation of topographic maps, aerial photographs, and soil surveys, as well as compiled published and unpublished geologic maps. The ages of deposits are estimated using landform shape, relative geomorphic position, cross-cutting relationships, superposition, depth and degree of surface dissection, and relative degree of soil profile development. Table 1.1 compares stratigraphic nomenclature used in Knudsen and others (2000b) and the CGS GIS database, with that of several previous studies performed in northern California.

Late Quaternary deposits cover the southwestern third of the quadrangle. Additional Quaternary deposits are mapped within canyons and upland drainages in the Berkeley Hills. Topographically higher, southeast-sloping Pleistocene alluvial fan surfaces (Qpf, Qof) at the base of the Berkeley Hills are incised by Holocene alluvial deposits (Qhf, Qha) that make their way to the historical shoreline of San Francisco Bay. The Pleistocene surfaces have been uplifted and are west of the active Hayward Fault zone. Along most of the coastline in the southeastern portion of the Oakland East Quadrangle artificial fill over Bay Mud (afbm) deposits extends from the historical shoreline to the present bay margin. Witter (unpublished) also mapped Pleistocene bay terrace deposits (Qbt) at the base of early to late Pleistocene alluvial fan deposits (Qof) in the southwestern corner of the quadrangle and along the shore of Lake Merritt (Plate 1.1).

The southeastern portion of Alameda Island within the quadrangle is primarily latest Pleistocene to Holocene dune sand (Qds), referred to as the Merritt Sand. This unit makes up the core of Alameda Island, which is then ringed by up to 1,500 horizontal feet of artificial fill over Bay Mud (afbm).
Some artificial channels (ac) have been built along the lower reaches of several creeks including: Temescal, Sausal, Peralta, an unnamed creek, and Arroyo Viejo. There are small bodies of engineered fill (af) mapped along Highways 24 and 13.

Holocene alluvial fan deposits have been subdivided by Witter (unpublished) into the following units: Qhc, Qhff, Qhf, and Qha. Qhc are modern channel deposits and are found within the banks of creeks. Qhff are fine-grained alluvial fan deposits exposed at the distal parts of fans. Qhf are alluvial fan deposits mapped along the majority of the west-southwest sloping east bay plain. Qha are undifferentiated alluvial deposits generally mapped within upland drainages and canyons.

The bedrock geology of the area is associated with a series of oceanic crust and volcanic arc terranes that were accreted to the continent during Mesozoic and Cenozoic time, and further deformed by transpression along the Hayward Fault zone during the Cenozoic. The oldest mapped geologic units are rocks that make up the Jurassic Coast Range Ophiolite (Graymer and others, 1996). Additional units include the Late Jurassic-Early Cretaceous Franciscan Complex, the Late Jurassic-Early Cretaceous Knoxville Formation (KJk), the Late Cretaceous Great Valley Sequence, and numerous Tertiary sedimentary and volcanic units. See the earthquake-induced landslide portion (Section 2) of this report for additional description of bedrock geology.

Notes:
(1) Not mapped at surface but unit interpreted in the subsurface.

Table 1.1. **Correlation of Quaternary Stratigraphic Nomenclatures Used within the Oakland East Quadrangle.** For this study, CGS has adopted the nomenclature of Knudsen and others (2000b).

**Structural Geology**

The Oakland East Quadrangle is within the active San Andreas Fault system, which distributes shearing across a complex system of primarily northwest-trending, right-lateral, strike-slip faults that include the San Andreas, Hayward, and Calaveras faults. The Hayward Fault extends northwest-southeast through the center of the quadrangle passing beneath Mills College, Lake Temescal, and U.C. Berkeley Memorial Stadium.
The Calaveras Fault is approximately 6 miles east of the eastern border of the quadrangle, and the San Andreas Fault is about 16 miles to the southwest. Historical ground-surface rupturing earthquakes have occurred on all of these faults (Lawson, 1908; Keefer and others, 1980). In addition to the previously listed faults, the Concord-Green Valley, Mt. Diablo Thrust, and Greenville faults will also contribute, over the long term, to the release of almost all of the seismic moment in the San Francisco Bay Area (WGCEP, 1999). The Concord-Green Valley, Mt. Diablo Thrust, and Greenville faults are located approximately 9, 9.5, and 14 miles east of the eastern border of the quadrangle, respectively.

ENGINEERING GEOLOGY

Information on subsurface geology and engineering characteristics of flatland deposits was obtained from borehole logs collected from reports on geotechnical and environmental projects. For this investigation, 198 borehole logs were collected from the files of the California Department of Transportation (CalTrans), City of Oakland Public Works Department, URS Greiner Woodward Clyde, William Lettis and Associates, Alan Kropp and Associates, and Alameda County Water District. Data from 173 borehole logs were entered into a CGS geotechnical GIS database (see Plate 1.2). Twelve cone penetrometer (CPT) soundings were obtained from the U.S. Geological Survey, which collected the data under the direction of Tom Holzer and Mike Bennett.

Standard Penetration Tests (SPTs) provide a standardized measure of the penetration resistance of geologic deposits and are commonly used as an index of soil density. This in-field test consists of counting the number of blows required to drive a split-spoon sampler (1.375-inch inside diameter) one foot into the soil at the bottom of a borehole at chosen intervals while drilling. The driving force is provided by dropping a 140-pound hammer weight 30 inches. The SPT method is formally defined and specified by the American Society for Testing and Materials in test method D1586 (ASTM, 1999). Recorded blow counts for non-SPT geotechnical sampling where the sampler diameter, hammer weight or drop distance differ from those specified for an SPT (ASTM D1586), are converted to SPT-equivalent blow counts. The actual and converted SPT blow counts are normalized to a common-reference, effective-overburden pressure of one atmosphere (approximately one ton per square foot) and a hammer efficiency of 60 percent using a method described by Seed and Idriss (1982) and Seed and others (1985). This normalized blow count is referred to as \( N_{1,60} \).

Geotechnical borehole logs provided information on lithologic and engineering characteristics of 1,955 cumulative feet of Holocene materials and 3,316 total feet of Pleistocene materials penetrated by boreholes analyzed for this study. Geotechnical characteristics of the Quaternary map units are summarized in Tables 1.2 and 1.3. Analysis of these data leads to recognition of certain characteristics and relationships among the units, including: 1) median values for penetration resistance suggest Holocene materials are less dense and more readily penetrated than Pleistocene materials; 2) penetration resistance values measured from the same map unit can vary considerably, the standard deviation is often 50 to 100 percent of the mean; 3) most alluvial fan deposits are fine grained; 4) Holocene units consist of both fine- and coarse-grained
materials, but have sand lenses throughout that have the potential to liquefy; and 5) late Pleistocene to Holocene dune sand (Qds) is primarily coarse grained with a wide range of penetration resistance values. Not shown in Tables 1.2 and 1.3 is the common occurrence of gravel within units generally of Pleistocene age.

Notes:
(1) Susceptibility assignments are specific to the materials within the Oakland East 7.5-Minute Quadrangle.
(2) Unified Soil Classification System.
(3) Based on the Simplified Procedure (Seed and Idriss, 1971; Youd and Idriss, 1997) and a small number of borehole analyses for some units.
(4) The liquefaction susceptibility of artificial fill ranges widely, depending largely on the nature of the fill, its age, and whether it was compacted during emplacement.
(5) n/a = not applicable

Table 1.3.  Liquefaction Susceptibility for Quaternary Map Units within the Oakland East 7.5-Minute Quadrangle. The category indicates relative susceptibility of deposits to liquefaction as a function of material type and ground-water depth within that deposit. VH = very high, H = high, M = moderate, L = low, and VL = very low to none.
GROUND WATER

Liquefaction hazard may exist in areas where depth to ground water is 40 feet or less. CGS uses the highest known ground-water levels because water levels during an earthquake cannot be anticipated because of the unpredictable fluctuations caused by natural processes and human activities. A historical-high ground-water map differs from most ground-water maps, which show the actual water table at a particular time. Plate 1.2 depicts hypothetical, historically high, ground-water levels within alluviated areas.

Ground-water conditions were investigated in the Oakland East Quadrangle to evaluate the depth to saturated materials. Saturated conditions reduce the effective normal stress, thereby increasing the likelihood of earthquake-induced liquefaction (Youd, 1973). The evaluation was based on first-encountered water noted in geotechnical borehole logs acquired from Alameda County Water District, City of Oakland, City of San Leandro, City of Alameda, Alameda County Public Works Department, and the State Water Resources Control Board. The depths to first-encountered unconfined ground water were plotted onto a map of the project area to display estimated historically shallowest ground water. Water depths from boreholes known to penetrate confined aquifers were not utilized.

Regional ground-water contours on Plate 1.2 show historical-high water depths, as interpreted from borehole logs from investigations between the 1950’s and the year 1999. Depths to first-encountered water range from 0 to 35 feet below the ground surface (Plate 1.2). In general, ground-water levels are shallow in the Oakland East Quadrangle. They are shallowest close to the San Francisco Bay margins and deepest (greater than 10 feet) along the Berkeley Hills range front (Plate 1.2). Boreholes within Alameda Island indicate an area of depressed (deeper than 10 feet) ground water in the center of the island, but depths to ground water are commonly less than 10 feet.

PART II

LIQUEFACTION POTENTIAL

Liquefaction may occur in water-saturated sediment during moderate to great earthquakes. Liquefied sediment loses strength and may fail, causing damage to buildings, bridges, and other structures. Many methods for mapping liquefaction hazard have been proposed. Youd (1991) highlights the principal developments and notes some of the widely used criteria. Youd and Perkins (1978) demonstrate the use of geologic criteria as a qualitative characterization of liquefaction susceptibility and introduce the mapping technique of combining a liquefaction susceptibility map and a liquefaction opportunity map to produce a liquefaction potential map. Liquefaction susceptibility is a function of the capacity of sediment to resist liquefaction. Liquefaction opportunity is a function of the potential seismic ground shaking intensity.
The method applied in this study for evaluating liquefaction potential is similar to that of Tinsley and others (1985). Tinsley and others (1985) applied a combination of the techniques used by Seed and others (1983) and Youd and Perkins (1978) for their mapping of liquefaction hazards in the Los Angeles region. CGS’s method combines geotechnical analyses, geologic and hydrologic mapping, and probabilistic earthquake shaking estimates, but follows criteria adopted by the SMGB (DOC, 2000).

LIQUEFACTION SUSCEPTIBILITY

Liquefaction susceptibility reflects the relative resistance of a soil to loss of strength when subjected to ground shaking. Physical properties of soil such as sediment grain-size distribution, compaction, cementation, saturation, and depth govern the degree of resistance to liquefaction. Some of these properties can be correlated to a sediment’s geologic age and environment of deposition. With increasing age, relative density generally will increase through cementation of the particles or compaction caused by the weight of the overlying sediment. Grain-size characteristics of a soil also influence susceptibility to liquefaction. Sand is more susceptible than silt or gravel, although silt of low plasticity is treated as liquefiable in this investigation. Cohesive soils generally are not considered susceptible to liquefaction. Such soils may be vulnerable to strength loss with remolding and represent a hazard that is not addressed in this investigation. Soil characteristics and processes that result in higher measured penetration resistances generally indicate lower liquefaction susceptibility. Thus, blow count and cone penetrometer values are useful indicators of liquefaction susceptibility.

Saturation is required for liquefaction, and the liquefaction susceptibility of a soil varies with the depth to ground water. Very shallow ground water increases the susceptibility to liquefaction (soil is more likely to liquefy). Soils that lack resistance (susceptible soils) typically are saturated, loose and sandy. Soils resistant to liquefaction include all soil types that are dry, cohesive, or sufficiently dense.

CGS’s map inventory of areas containing soils susceptible to liquefaction begins with evaluation of geologic maps and historical occurrences, cross-sections, geotechnical test data, geomorphology, and ground-water hydrology. Soil properties and soil conditions such as type, age, texture, color, and consistency, along with historical depths to ground water are used to identify, characterize, and correlate susceptible soils. Because Quaternary geologic mapping is based on similar soil observations, liquefaction susceptibility maps typically are similar to Quaternary geologic maps. CGS’s qualitative relations among susceptibility, geologic map unit and depth to ground water are summarized in Table 1.3.

Most Holocene materials where water levels are within 30 feet of the ground surface have susceptibility assignments of high (H) to very high (VH) (Table 1.3). Holocene San Francisco Bay Mud (Qhbm), Holocene alluvial fan fine facies deposits (Qhff), and undifferentiated Holocene alluvium (Qha) are primarily composed of fine-grained material and are assigned moderate susceptibility. However, these units may contain lenses of material with higher liquefaction susceptibility. All latest Pleistocene and older
deposits within 30 feet of the ground surface have low (L) susceptibility assignments except late Pleistocene to Holocene alluvial fan deposits (Qf) and latest Pleistocene to Holocene dune sand (Qds). This unit (Qf) is relatively thin in the Oakland East Quadrangle but may have low densities along with lenses of potentially liquefiable material that could liquefy if saturated (Table 1.3). It is, therefore, assigned moderate susceptibility. Latest Pleistocene to Holocene dune sand (Qds) has a moderate (M) susceptibility assignment where it is saturated above 10 feet. All other units have low (L) to (VL) susceptibility assignments within 40 feet of the ground surface.

LIQUEFACTION OPPORTUNITY

Liquefaction opportunity is a measure, expressed in probabilistic terms, of the potential for strong ground shaking. Analyses of in-situ liquefaction resistance require assessment of liquefaction opportunity. The minimum level of seismic excitation to be used for such purposes is the level of peak ground acceleration (PGA) with a 10 percent probability of exceedance over a 50-year period (DOC, 2000). The earthquake magnitude used in CGS’s analysis is the magnitude that contributes most to the calculated PGA for an area.

For the Oakland East Quadrangle, PGAs of 0.58 g to 0.94 g, resulting from an earthquake of magnitude 7.1, were used for liquefaction analyses. The PGA and magnitude values were based on de-aggregation of the probabilistic hazard at the 10 percent in 50-year hazard level (Petersen and others, 1996). See the ground motion section (3) of this report for additional information.

Quantitative Liquefaction Analysis

CGS performs quantitative analysis of geotechnical data to evaluate liquefaction potential using the Seed-Idriss Simplified Procedure (Seed and Idriss, 1971; Seed and others, 1983; National Research Council, 1985; Seed and others, 1985; Seed and Harder, 1990; Youd and Idriss, 1997; Youd and others, 2001). Using the Seed-Idriss Simplified Procedure one can calculate soil resistance to liquefaction, expressed in terms of cyclic resistance ratio (CRR), based on SPT results, ground-water level, soil density, moisture content, soil type, and sample depth. CRR values are then compared to calculated earthquake-generated shear stresses expressed in terms of cyclic stress ratio (CSR). The Seed-Idriss Simplified Procedure requires normalizing earthquake loading relative to a M7.5 event for the liquefaction analysis. To accomplish this, CGS’s analysis uses the Idriss magnitude-scaling factor (MSF) (Youd and Idriss, 1997). It is convenient to think in terms of a factor of safety (FS) relative to liquefaction, where: FS = (CRR / CSR) * MSF. FS, therefore, is a quantitative measure of liquefaction potential. CGS uses a factor of safety of 1.0 or less, where CSR equals or exceeds CRR, to indicate the presence of potentially liquefiable soil. While an FS of 1.0 is considered the “trigger” for liquefaction, for a site specific analysis an FS of as much as 1.5 may be appropriate depending on the vulnerability of the site and related structures.

The CGS liquefaction analysis program calculates an FS for each geotechnical sample where blow counts were collected. Typically, multiple samples are collected for each borehole. The program then independently calculates an FS for each non-clay layer that
includes at least one penetration test using the minimum \((N_1)_{60}\) value for that layer. The minimum FS value of the layers penetrated by the borehole is used to determine the liquefaction potential for each borehole location. The reliability of FS values varies according to the quality of the geotechnical data. FS, as well as other considerations such as slope, presence of free faces, and thickness and depth of potentially liquefiable soil, are evaluated in order to construct liquefaction potential maps, which are then used to make a map showing zones of required investigation.

Of the 173 geotechnical borehole logs reviewed in this study (Plate 1.2), most include blow-count data from SPTs or from penetration tests that allow reasonable blow count translations to SPT-equivalent values. Non-SPT values, such as those resulting from the use of 2-inch or 2½-inch inside-diameter ring samplers, were translated to SPT-equivalent values if reasonable factors could be used in conversion calculations. The reliability of the SPT-equivalent values varies. Therefore, they are weighted and used in a more qualitative manner. Few borehole logs, however, include all of the information (e.g. soil density, moisture content, sieve analysis, etc.) required for an ideal Seed-Idriss Simplified Procedure. For boreholes having acceptable penetration tests, liquefaction analysis is performed using recorded density, moisture, and sieve test values or using averaged test values of similar materials.

The Seed-Idriss Simplified Procedure for liquefaction evaluation was developed primarily for clean sand and silty sand. As described above, results depend greatly on accurate evaluation of in-situ soil density as measured by the number of soil penetration blow counts using an SPT sampler. However, many of the Holocene alluvial deposits in the study area contain a significant amount of gravel. In the past, gravelly soils were considered not to be susceptible to liquefaction because the high permeability of these soils presumably would allow the dissipation of pore pressures before liquefaction could occur. However, liquefaction in gravelly soils has been observed during earthquakes, and recent laboratory studies have shown that gravelly soils are susceptible to liquefaction (Ishihara, 1985; Harder and Seed, 1986; Budiman and Mohammadi, 1995; Evans and Zhou, 1995; and Sy and others, 1995). SPT-derived density measurements in gravelly soils are unreliable and generally too high. They are likely to lead to overestimation of the density of the soil and, therefore, result in an underestimation of the liquefaction susceptibility. To identify potentially liquefiable units where the N values appear to have been affected by gravel content, correlations were made with boreholes in the same unit where the N values do not appear to have been affected by gravel content.

**LIQUEFACTION ZONES**

**Criteria for Zoning**

Areas underlain by materials susceptible to liquefaction during an earthquake were included in liquefaction zones using criteria developed by the Seismic Hazards Mapping Act Advisory Committee and adopted by the SMGB (DOC, 2000). Under those guideline criteria, liquefaction zones are areas meeting one or more of the following:
1. Areas known to have experienced liquefaction during historical earthquakes

2. All areas of uncompacted artificial fill containing liquefaction-susceptible material that are saturated, nearly saturated, or may be expected to become saturated

3. Areas where sufficient existing geotechnical data and analyses indicate that the soils are potentially liquefiable

4. Areas where existing geotechnical data are insufficient

In areas of limited or no geotechnical data, susceptibility zones may be identified by geologic criteria as follows:

   a) Areas containing soil deposits of late Holocene age (current river channels and their historic floodplains, marshes and estuaries), where the M7.5-weighted peak acceleration that has a 10 percent probability of being exceeded in 50 years is greater than or equal to 0.10 g and the water table is less than 40 feet below the ground surface; or

   b) Areas containing soil deposits of Holocene age (less than 11,000 years), where the M7.5-weighted peak acceleration that has a 10 percent probability of being exceeded in 50 years is greater than or equal to 0.20 g and the historical high water table is less than or equal to 30 feet below the ground surface; or

   c) Areas containing soil deposits of latest Pleistocene age (11,000 to 15,000 years), where the M7.5-weighted peak acceleration that has a 10 percent probability of being exceeded in 50 years is greater than or equal to 0.30 g and the historical high water table is less than or equal to 20 feet below the ground surface.

Application of SMGB criteria to liquefaction zoning in the Oakland East Quadrangle is summarized below.

**Areas of Past Liquefaction**

Knudsen and others (2000b) compiled data from Tinsley and others (1998), and Youd and Hoose (1978) and released this information as a digital database. Tinsley and others (1998) compiled information from the 1989 Loma Prieta earthquake and Youd and Hoose (1978) compiled information from the 1868 and 1906 earthquakes. The digital database differs from earlier compilation efforts in that the observations were located on a 1:24,000-scale base map versus the smaller scale base maps used in the earlier publications. Sites were reevaluated and some single sites were broken into two or more where the greater base map scale allowed.

Within the Oakland East Quadrangle, Youd and Hoose (1978) identified one historical liquefaction site, a one- to several-foot drop in “made ground” at Mills College in the 1906 earthquake (site 173, Plate 1.2), recorded following the 1906 earthquake by Lawson (1908). This settlement was on local fill and the underlying and surrounding Holocene geologic units are not considered likely to liquefy in this area as they are unsaturated.
Artificial Fills

In the Oakland East Quadrangle, artificial fill areas large enough to show at the scale of mapping consist of engineered fill for river levees and elevated freeways. Since these fills are considered to be properly engineered, zoning for liquefaction in such areas depends on soil conditions in underlying strata. Non-engineered fills are commonly loose and uncompacted, and the material varies in size and type. Artificial fill over Bay Mud (afbm) is extensive as a result of the practice of in-filling of the natural Bay margins. Artificial fill over Bay Mud (afbm) is extensive west of the BART tracks in the southwestern corner of the quadrangle, as well as the shoreline of both San Francisco Bay and Lake Merritt. Government Island located within the Oakland Inner Harbor is entirely composed of artificial fill over Bay Mud (afbm). Because this unit has hosted a large fraction of historical occurrences (Knudsen and others, 2000a), all areas mapped as afbm are included in the zone of required investigation.

Areas with Sufficient Existing Geotechnical Data

Borehole logs that include penetration test data and sufficiently detailed lithologic descriptions were used to evaluate liquefaction potential as determined by the Seed-Idriss Simplified Procedure. In Holocene alluvial deposits (Qhf, Qhff), artificial fill over Bay Mud (afbm), and latest Pleistocene to Holocene dune sand (Qds) that cover much of flatland area, most of the borehole logs that were analyzed using the Seed-Idriss Simplified Procedure contain sediment layers that may liquefy under the expected earthquake loading. These areas containing saturated potentially liquefiable material included in the zone.

Geotechnical data for Holocene alluvial fan deposits (Qhf) in the area of East Oakland show that only a relatively small percentage of the unit is loose and coarse grained as well as being saturated. The liquefaction zone boundary extending from Peralta Creek to the southern border of the Oakland East Quadrangle (excluding the sections along stream channels) is the surface projection of the contact between ground water and the base of Holocene fan deposits (Qhf). Where lower density, younger material is above the water table (i.e. unsaturated) and only denser Pleistocene material is saturated, these areas are excluded from the zone. The previous method of mapping utilized geologic contacts as liquefaction zone boundaries. The current liquefaction zone line is farther to the northeast and includes a larger area of the alluvial fan within the zone.

The area along Arroyo Viejo was originally included in the liquefaction zone based on earlier Quaternary geologic mapping that identified it as a Holocene alluvial fan levee deposit (Qhl). New mapping indicates no levee deposit exists in this area. Therefore, this area along Arroyo Viejo, outside of the stream channel deposits, has been removed from the liquefaction zone.

Areas with Insufficient Existing Geotechnical Data

Adequate geotechnical borehole information for artificial and modern stream channel deposits (ac and Qhc) and undifferentiated Holocene alluvium (Qha), generally is lacking
in most areas. These deposits, therefore, are evaluated and included or excluded from the liquefaction zone for reasons presented in criteria 4-a, and 4-b, above. In the Oakland East Quadrangle, ground water and forecast ground motions are sufficiently high to include these Holocene units within the liquefaction zone. These deposits are along upland creeks and canyons that are likely to contain loose, granular, late Holocene material that is saturated because of the proximity of active stream channels. Latest Pleistocene to Holocene alluvial fan deposits (Qf) do not contain adequate borehole information within the Oakland East Quadrangle, however, this unit is excluded from the zone based on field examinations, thickness of the deposit, and its properties in neighboring quadrangles.

ACKNOWLEDGMENTS

The authors would like to thank personnel with the Cities of Alameda, Albany, Berkeley, Emeryville, and for their assistance with data collection efforts; Chris Hitchcock and Rob Witter from William Lettis and Associates, who provided additional reports from monitoring wells collected from the Alameda County Water District, and geologic mapping and discussion, respectively; Alan Kropp of Alan Kropp and Associates who provided access to his files; and Tom Holzer and Michael Bennett of the U.S. Geological Survey who provided CPT data and important geologic discussion and information. At CGS, special thanks to Ralph Loyd and Al Barrows for their technical review; Marvin Woods, Teri McGuire, Bob Moskovitz and Barbara Wanish for their GIS operations support; Luis Acedo for assistance with input of geotechnical borehole data into the database; Christopher Wills for geologic investigation; and Ross Martin and Barbara Wanish for their help with preparation of the graphical liquefaction zone map for this report.

SECTION 2
EARTHQUAKE-INDUCED LANDSLIDE
EVALUATION REPORT

Earthquake-Induced Landslide Zones in the
Oakland East 7.5-Minute Quadrangle,
Alameda County, California

By
Rick I. Wilson, Mark O. Wiegers, Timothy P. McCrink, Wayne D.
Haydon, and Jack R. McMillan

California Department of Conservation
California Geological Survey

PURPOSE

The Seismic Hazards Mapping Act (the Act) of 1990 (Public Resources Code, Chapter 7.8, Division 2) directs the California Department of Conservation (DOC), Division of Mines and Geology (DMG) [now called California Geological Survey (CGS)] to delineate Seismic Hazard Zones. The purpose of the Act is to reduce the threat to public health and safety and to minimize the loss of life and property by identifying and mitigating seismic hazards. Cities, counties, and state agencies are directed to use seismic hazard zone maps prepared by CGS in their land-use planning and permitting processes. The Act requires that site-specific geotechnical investigations be performed prior to permitting most urban development projects within the hazard zones. Evaluation and mitigation of seismic hazards are to be conducted under guidelines established by the California State Mining and Geology Board (DOC, 1997). The text of this report is on the Internet at http://gmw.consrv.ca.gov/shmp/webdocs/sp117.pdf
Following the release of DMG Special Publication 117 (DOC, 1997), agencies in the Los Angeles metropolitan region sought more definitive guidance in the review of geotechnical investigations addressing landslide hazards. The agencies made their request through the Geotechnical Engineering Group of the Los Angeles Section of the American Society of Civil Engineers (ASCE). This group convened an implementation committee in 1998 under the auspices of the Southern California Earthquake Center (SCEC). The committee, which consisted of practicing geotechnical engineers and engineering geologists, released an overview of the practice of landslide analysis, evaluation, and mitigation techniques (SCEC, 2002). This text is also on the Internet at: http://www.scec.org/

This section of the evaluation report summarizes seismic hazard zone mapping for earthquake-induced landslides in the Alameda County portion of the Oakland East 7.5-Minute Quadrangle. Section 1 (addressing liquefaction) and Section 3 (addressing earthquake shaking), complete the report, which is one of a series that summarizes the preparation of seismic hazard zone maps within the state (Smith, 1996). Additional information on seismic hazard zone mapping in California can be accessed on the California Geological Survey's Internet page: http://www.conservation.ca.gov/CGS/index.htm

BACKGROUND

Landslides triggered by earthquakes historically have been a significant cause of earthquake damage. In California, large earthquakes such as the 1971 San Fernando, 1989 Loma Prieta, and 1994 Northridge earthquakes triggered landslides that were responsible for destroying or damaging numerous structures, blocking major transportation corridors, and damaging life-line infrastructure. Areas that are most susceptible to earthquake-induced landslides are steep slopes in poorly cemented or highly fractured rocks, areas underlain by loose, weak soils, and areas on or adjacent to existing landslide deposits. These geologic and terrain conditions exist in many parts of California, including numerous hillside areas that have already been developed or are likely to be developed in the future. The opportunity for strong earthquake ground shaking is high in many parts of California because of the presence of numerous active faults. The combination of these factors constitutes a significant seismic hazard throughout much of California, including the hillside areas in the cities of Berkeley and Oakland in the Oakland East Quadrangle.

METHODS SUMMARY

The mapping of earthquake-induced landslide hazard zones presented in this report is based on the best available terrain, geologic, geotechnical, and seismological data. If unavailable or significantly outdated, new forms of these data were compiled or generated specifically for this project. The following were collected or generated for this evaluation:
Digital terrain data were used to provide an up-to-date representation of slope gradient and slope aspect in the study area.

Geologic mapping was used to provide an accurate representation of the spatial distribution of geologic materials in the study area. In addition, a map of existing landslides, whether triggered by earthquakes or not, was prepared.

Geotechnical laboratory test data were collected and statistically analyzed to quantitatively characterize the strength properties and dynamic slope stability of geologic materials in the study area.

Seismological data in the form of CGS probabilistic shaking maps and catalogs of strong-motion records were used to characterize future earthquake shaking within the mapped area.

The data collected for this evaluation were processed into a series of GIS layers using commercially available software. A slope stability analysis was performed using the Newmark method of analysis (Newmark, 1965), resulting in a map of landslide hazard potential. The earthquake-induced landslide hazard zone was derived from the landslide hazard potential map according to criteria developed in a CGS pilot study (McCrink and Real, 1996; McCrink, 2001) and adopted by the State Mining and Geology Board (DOC, 2000).

SCOPE AND LIMITATIONS

The methodology used to make this map is based on earthquake ground-shaking estimates, geologic material-strength characteristics and slope gradient. These data are gathered from a variety of outside sources. Although the selection of data used in this evaluation was rigorous, the quality of the data is variable. The State of California and the Department of Conservation make no representations or warranties regarding the accuracy of the data gathered from outside sources.

Earthquake-induced landslide zone maps are intended to prompt more detailed, site-specific geotechnical investigations as required by the Act. As such, these zone maps identify areas where the potential for earthquake-induced landslides is relatively high. Due to limitations in methodology, it should be noted that these zone maps do not necessarily capture all potential earthquake-induced landslide hazards. Earthquake-induced ground failures that are not addressed by this map include those associated with ridge-top spreading and shattered ridges. It should also be noted that no attempt has been made to map potential run-out areas of triggered landslides. It is possible that such run-out areas may extend beyond the zone boundaries. The potential for ground failure resulting from liquefaction-induced lateral spreading of alluvial materials, considered by some to be a form of landsliding, is not specifically addressed by the earthquake-induced landslide zone or this report. See Section 1, Liquefaction Evaluation Report for the Oakland East Quadrangle, for more information on the delineation of liquefaction zones.
This map covers only the portion of the Oakland East Quadrangle that lies within Alameda County and a strip of the Las Trampas Ridge Quadrangle to the east where a part of the City of Oakland extends. Seismic Hazard Zone maps will be prepared for Contra Costa County at a later date. In addition, the seismic hazard zone map does not include Redwood Regional Park or Anthony Chabot Regional Park in Alameda County because development within these parks is not anticipated. Official Seismic Hazard Zone maps covering the cities of Oakland and Piedmont were prepared in 1999 and released in March 2000 (DOC, 1999). The most significant change to this earlier zone map is the preparation of earthquake-induced landslide zones of required investigation for the City of Berkeley at the northwesternmost edge of the quadrangle. Other changes include the addition of several newly recognized landslides on the Oakland-Berkeley boundary, and changes to the landslide zones along stream channels reflecting changes to the Quaternary geologic map and the liquefaction zone.

The remainder of this report describes in more detail the mapping data and processes used to prepare the earthquake-induced landslide zone map for the Oakland East Quadrangle. The information is presented in two parts. Part I covers physiographic, geologic and engineering geologic conditions in the study area. Part II covers the preparation of landslide hazard potential and landslide zone maps.

PART I

PHYSIOGRAPHY

Study Area Location and Physiography

The Oakland East 7.5-Minute Quadrangle lies on the eastern side of San Francisco Bay. Within this quadrangle, the cities of Oakland and Berkeley are contiguous and occupy flatlands along the margin of the bay and steep hilly areas in the Oakland-Berkeley Hills. Piedmont occupies a low hilly area on the east side of Oakland. Alameda occupies an island in San Francisco Bay that is separated from Oakland by a tidal channel.

The area encompassed by Oakland, Piedmont, Berkeley and Alameda covers approximately one-half of the southern and western side of the Oakland East Quadrangle. The remainder of the quadrangle covers Contra Costa County and Redwood Park and Anthony Chabot Regional Park. These areas are not currently covered by the seismic hazard zone map.

The flatland areas in Oakland, Berkeley and Alameda are heavily developed for residential and commercial use. Many of the hilly areas in Oakland, Berkeley and Piedmont also have been developed for residential use. Hillside areas are accessed by a system of steep, winding roads.

Elevations in the map area range from sea level along the shore of San Francisco Bay to more than 1,500 feet along the crest of the Oakland-Berkeley Hills. The Oakland-
Berkeley Hills are drained by numerous creeks that extend westward across the alluvial plain to San Francisco Bay, including Palo Seco Creek, Peralta Creek, Redwood Creek, Sausal Creek, Shephard Creek, Temescal Creek and Arroyo Viejo.

Major highways include Interstate 880 along the shoreline of San Francisco Bay, Interstate 580 through the central part of Oakland, State Highway 13 between Berkeley and Oakland and State Highway 24 that extends east from Berkeley and Oakland through the Caldecut Tunnel to Contra Costa County.

Digital Terrain Data

The calculation of slope gradient is an essential part of the evaluation of slope stability under earthquake conditions. An accurate slope gradient calculation begins with an up-to-date map representation of the earth’s surface in the form of a digital topographic map. Within the City of Berkeley, digital topography in the form of a Level 2 digital elevation model (DEM) was obtained from the USGS (U.S. Geological Survey, 1993). This DEM, prepared from the 7.5-minute quadrangle topographic contours based on 1958 aerial photography, has a 10-meter horizontal resolution and a 7.5-meter vertical accuracy.

Digital topography within the City of Oakland relied on a set of digital terrain files obtained from the City of Oakland. These files contained digitized contours, breaklines, and spot elevations that were collected from stereo-pair aerial photography flown in 1994. The files were first translated into a format usable by CGS and then converted to a triangular-irregular-network (TIN) computer model. Finally, they were converted into a regularly spaced digital elevation model (DEM) with a 10-meter horizontal resolution and a vertical accuracy estimated to be on the order of 1 to 2 meters.

A slope map was made from the corrected DEM using a third-order, finite difference, center-weighted algorithm (Horn, 1981). The slope map was used first in conjunction with the aspect map and geologic structural data to identify areas of potential adverse bedding conditions, and then again with the geologic strength map in the preparation of the earthquake-induced landslide hazard potential map.

GEOLOGY

Bedrock and Surficial Geology

The primary source of bedrock geology used in this slope stability evaluation is the geologic map and map database of the Oakland metropolitan area by Graymer (2000). This digital geologic database was compiled at a resolution of 1:24,000 from previously published reports and from new mapping and field checking by Graymer (2000). Geologic mapping by Radbruch (1969) also was reviewed during this project. Witter (unpublished) prepared a Quaternary surficial deposits geologic map at a scale of 1:24,000. Surficial geology is discussed in detail in Section 1 of this report. CGS geologists merged the surficial and bedrock geologic maps, and contacts between surficial and bedrock units were modified in some areas to resolve differences between
the two maps. Geologic field reconnaissance was performed to assist in adjusting
contacts and to review the lithology and structure of the various geologic units.

The bedrock geology of the Oakland/Piedmont area is associated with a series of oceanic
crust and volcanic arc terranes that were accreted to the continent during Mesozoic and
Cenozoic time and further deformed by transpression along the Hayward Fault zone
during the Cenozoic. The oldest mapped geologic units are rocks that comprise the
Jurassic Coast Range Ophiolite. The ophiolitic rocks consist of serpentinite (map symbol
sp; Graymer and others, 2000), gabbro (Jgb and gb), massive basalt and diabase (Jb), and
pillow and brecciated basalt with minor diabase (Jpb). Overlying the ophiolitic rocks are
highly altered intermediate and silicic volcanic rocks known as keratophyre (Jsv).

Radbruch (1969) previously mapped this unit as the Tertiary Leona Rhyolite but later
investigation by Jones and Curtis (1991) revealed that these rocks are Late Jurassic.
According to Jones and Curtis (1991) the keratophyre is the probable altered remnant of a
volcanic arc deposited on the ophiolite. Both the ophiolite and keratophyre rocks crop
out throughout the eastern portion of the Oakland/Piedmont area.

The Late Jurassic-Early Cretaceous Franciscan Complex consists of a melange unit
(KJfm and fm), a predominantly sandstone unit (KJfs), a unit called the Novato Quarry
Terrane (Kfn), and an undivided unit (Kfj) (Graymer, 2000). The Franciscan melange is
composed of sheared black argillite, graywacke sandstone, and minor green tuff, with
blocks containing meta-graywacke (fs), chert (fc), serpentinite (sp and sp?), greenstone
(fg), and numerous other types of rock. The Franciscan sandstone consists of undivided
graywacke and meta-graywacke. The Novato Quarry Terrane is composed of distinctly
bedded to massive, mica-bearing lithic wacke. The Novato Quarry Terrane hosts a large
quartz diorite intrusion (Kfgm) in north Oakland on the east side of Broadway. The
quartz diorite is about 800 feet long by 500 feet wide and is partly bound by faults.
These units exist throughout the eastern half of the Oakland/Piedmont area with the most
notable Kfn encompassing almost the entire City of Piedmont.

The Late Jurassic-Early Cretaceous Knoxville Formation (KJk), unnamed Cretaceous
sandstone and shale units (Kss and Ksh, respectively), and the Late Cretaceous Great
Valley Sequence unconformably overlie the ophiolitic and keratophyre units (Graymer,
2000). The KJk consists of shale with thin sandstone interbeds that were deposited in a
shallow marine environment (Radbruch, 1957). The Kss and Ksh are composed of clasts
of predominately granitic origin. The Great Valley Sequence consists of a turbidite
sequence of sandstone, shale, and conglomerate that was deposited in a deep ocean
trench. The Great Valley Sequence is composed of several formations: the Joaquin
Miller Formation (Kjm), the Oakland Conglomerate (Ko), the Shephard Creek Formation
(Ksc), the Redwood Canyon Formation (Kr), the Pinehurst Shale (Kp), and an unnamed
sedimentary rock unit (Ku) (Graymer, 2000). All but the KJk, Kss, Ksh, and Ku exist
along the southeastern boundary of the City of Oakland; the KJk exists throughout the
eastern half of the area, and the Kss, Ksh, and Ku exist within the northeastern quarter of
the area.

Tertiary rocks unconformably rest on the older units in the northeastern quarter of the
Oakland/Piedmont area. The oldest rocks consist of an unnamed Paleocene glauconitic
sandstone unit (Ta), an unnamed Eocene mudstone unit (Tes), an unnamed Oligocene-Miocene glauconitic mudstone unit (Tsm) with a locally interbedded sandstone subunit (Tsms), and an unnamed early Miocene gray mudstone unit (Tush). Overlying these units in decreasing age are the following Tertiary formations:

- middle to late Miocene Claremont Chert (Tcc) with an interbedded sandstone subunit (Tccs and Tccs?)
- late Miocene Briones Formation (Tbr) composed of quartz-lithic sandstone and shell breccia
- late Miocene Orinda Formation (Tor) composed of non-marine conglomeratic and sandstone rocks
- late Miocene Moraga Formation (Tmb) composed of extrusive volcanic rocks
- late Miocene Siesta Formation (Tst) composed of non-marine siltstone and sandstone
- late Miocene Bald Peak Basalt (Tbp)
- unnamed late Miocene sedimentary and volcanic rocks (Tus)
- unnamed late Miocene-Pliocene sandstone unit (Tss)
- late Miocene-Pliocene Mullholland Formation (Tm), divided into an upper and lower member (Tmlu and Tmll, respectively), and composed of sandstone and mudstone (Graymer, 2000).

According to mapping by Helley and Graymer (1997), late Tertiary-Quaternary surficial deposits exist within the upland areas. The oldest of these is the Irvington Gravels of Savage (1951), QTi and QTi?, which crop out in small pockets in the southeastern quarter of the area and consist of cross-bedded sand and gravel.

Deposits of Pleistocene alluvial fan and terrace deposits have been uplifted and exposed west of the Hayward Fault in the low-lying foothills (Witter, unpublished). These include early to late Pleistocene alluvial fan deposits (Qof) and Pleistocene bay terrace deposits (Qbt). Holocene deposits that are exposed in the upland canyon areas, as well as some lowland drainages, include Holocene alluvial fan deposits (Qhf), undifferentiated Holocene alluvial fan deposits (Qha), and natural and artificial stream channel deposits (Qhc and ac, respectively; Witter, unpublished). Other younger deposits that are isolated to the lowland areas include late Pleistocene to Holocene dune sand (Qds), artificial fill over Bay Mud (afbm), and Holocene alluvial fan deposits, fine-grained facies (Qhff). A more detailed discussion of the Quaternary deposits can be found in Section 1.

**Structural Geology**

The bedrock structure in the Oakland-Berkeley Hills results from a complex deformational history. Deformation included Mesozoic and early Tertiary subduction
and accretion, early to mid-Tertiary uplift and attenuation faulting and, finally, a period of strike-slip and reverse faulting that began in the late Miocene and continues today.

The primary structure in the study area is the Hayward Fault, an active right-lateral strike-slip fault with an estimated slip rate of about 9mm per year. The Hayward Fault is actively creeping in Berkeley and other East Bay cities, as manifested by offset curbs, streets, buildings and other structures at numerous locations. The total slip on the Hayward Fault has been estimated to be about 95 km. (Graymer, 2000). Lienkaemper (1992) has mapped the inferred location of the active trace of the Hayward Fault in detail. Various other traces are shown on earlier geologic maps (Smith, 1980; Radbruch-Hall, 1974). Associated with the main trace are numerous splays and subsidiary traces that may accommodate secondary movements related to the main trace or which may be slightly older abandoned traces. Bedrock units in the vicinity of the Hayward Fault Zone have been complexly offset and juxtaposed along the main trace and it’s associated subsidiary traces.

There are additional faults in the Oakland East Quadrangle east of the Hayward Fault. The most prominent is the Moraga-Miller Creek-Palomares Fault zone. This fault is in the eastern part of the quadrangle, outside of the current area evaluated for seismic hazard zoning. The Moraga-Miller Creek-Palomares Fault is a transpressive fault which has had as much as 95 km of right-lateral offset since the late Miocene (Graymer, 2000). Between the Hayward Fault and the Moraga-Miller Creek-Palomares Fault are numerous east-vergent reverse faults, indicating significant compression between these two major transpressive faults. One other significant fault in the study area is the Chabot Fault, which extends into the southern part of the quadrangle east of the Hayward Fault. Unlike most of the other faults, the Chabot Fault displays a normal component of displacement, which indicates that there may have been localized and perhaps brief transtensional stress in the region (Graymer and others, 1996).

Bedrock units in the study area have been steeply tilted and strongly folded and generally dip moderately to steeply to the northeast and southwest. Several prominent northwest-trending fold axes are mapped in the eastern part of the quadrangle (Graymer, 2000).

Landslide Inventory

As a part of the geologic data compilation, an inventory of existing landslides in the Oakland East Quadrangle was prepared by field reconnaissance, analysis of stereo-paired aerial photographs (see Air Photos in References) and a review of previously published landslide mapping. Landslides were mapped at a scale of 1:24,000. For each landslide included on the map a number of characteristics (attributes) were compiled. These characteristics include the confidence of interpretation (definite, probable and questionable) and other properties, such as activity, thickness, and associated geologic unit(s). Landslides rated as definite and probable were carried into the landslide zoning as described later in this report. Landslides rated as questionable were not carried into the slope stability analysis due to the uncertainty of their existence. The completed landslide map was scanned, digitized, and the attributes were compiled in a database. A version of this landslide inventory is included with Plate 2.1.
For preparation of our landslide inventory, we reviewed pertinent sources including: Lawson (1914), Louderback (1951), Radbruch (1969), Taylor and Brabb (1972), Nilsen (1973 a, 1973b, 1975), Blake and others (1974), and Graymer and others (1996). Landslide features identified from these sources were re-evaluated during the aerial photograph interpretation and limited field reconnaissance conducted for this investigation. Some of the landslide features identified in the previous work were not included in the landslide inventory because during our re-evaluation it was concluded that some of the mapped features were not landslides. In other places, additional landslides were identified or the boundaries of many of the landslides were modified from the previous work. The landslide inventory also included review of records of historical landslide occurrences that were in the files of the City of Oakland. The City of Oakland has kept field memos and in some cases relatively detailed accounts of approximately 250 historical landslides. These files include landslides that have affected city and/or private properties over the years and that have required some response or action by the city. Many of these historical landslides are relatively small, affecting perhaps a single lot or short road segment. Though small, some required considerable expenditure to mitigate. A few of the historical landslides in Oakland are large and affected multiple homes and significant infrastructure. The two largest historical landslides, in terms of property damage, are the McKillop Road landslide near Central Reservoir that destroyed the sites of at least 14 homes in the 1950’s, and the Kitchener Court landslide near the Mormon Temple that destroyed the sites of at least 17 homes in the 1970’s. Scores of other landslides have damaged or destroyed homes in Oakland. All of the landslide events obtained from the City of Oakland files were interpreted as definite slope failures and were included in the inventory.

Landslides are abundant in the hillside areas of Oakland and Berkeley and have periodically damaged homes and other improvements. Landslides range from large, deep-seated features that may be several thousand feet across to small shallow debris/earth slides less than 100 feet in diameter. Deep-seated landslides, which are primarily mapped by geomorphic interpretation of aerial photographs, are characterized by benching, irregular terrain with anomalous drainage patterns. Some of these large features are dormant or relict features that likely originated thousands of years ago, in some cases perhaps in the Pleistocene. Some old deep-seated landslides have been historically active, periodically resulting in damage to structures or other improvements constructed on them.

ENGINEERING GEOLOGY

Geologic Material Strength

To evaluate the stability of geologic materials under earthquake conditions, the geologic map units described above were ranked and grouped on the basis of their shear strength. Generally, the primary source for shear-strength measurements is geotechnical reports prepared by consultants on file with local government permitting departments. Shear-strength data for the units identified on the Oakland East Quadrangle geologic map were obtained from cities of Berkeley, Oakland and Piedmont, Alameda County, the
University of California at Berkeley, Lawrence Berkeley Laboratory, Berlogar Geotechnical Consultants, Harza Engineering Company, and the CGS Environmental Review Project (see Appendix A). The locations of rock and soil samples taken for shear testing within the Oakland East Quadrangle are shown on Plate 2.1. Shear tests from the adjoining Richmond, Briones Valley, Oakland West, San Leandro and Hayward quadrangles were used to augment data for several geologic formations for which little or no shear test information was available within the Oakland East Quadrangle.

Shear strength data gathered from the above sources were compiled for each geologic map unit. Geologic units were grouped on the basis of average angle of internal friction (average phi) and lithologic character. Average (mean or median) phi values for each geologic map unit and corresponding strength group are summarized in Table 2.1. For most of the geologic strength groups in the map area, a single shear strength value was assigned and used in our slope stability analysis. A geologic material strength map was made based on the groupings presented in Tables 2.1 and 2.2, and this map provides a spatial representation of material strength for use in the slope stability analysis.

A number of geologic formations were subdivided into different strength groups, as described below.

**Adverse Bedding Conditions**

Adverse bedding conditions are an important consideration in slope stability analyses. Adverse bedding conditions occur where the dip direction of bedded sedimentary rocks is roughly the same as the slope aspect, and where the dip magnitude is less than the slope gradient. Under these conditions, landslides can slip along bedding surfaces due to a lack of lateral support.

To account for adverse bedding in our slope stability evaluation, we used geologic structural data in combination with digital terrain data to identify areas with potentially adverse bedding, using methods similar to those of Brabb (1983). The structural data, derived from the geologic map database, was used to categorize areas of common bedding dip direction and magnitude. The dip direction was then compared to the slope aspect and, if the same, the dip magnitude and slope gradient categories were compared. If the dip magnitude category was less than or equal to the slope gradient category, but greater than 25 percent (4:1 slope), the area was marked as a potential adverse bedding area.

Most formations within the Alameda County portion of the Oakland East Quadrangle were found to have stratigraphic and material strength characteristics conducive to adverse bedding conditions. These formations, which contain interbedded sandstone and shale, were subdivided based on shear strength differences between coarse-grained (higher strength) and fine-grained (lower strength) lithologies. Shear strength values for the coarse- and fine-grained lithologies were then applied to areas of favorable and adverse bedding orientation, respectively, which were determined from structural and terrain data as discussed above. It was assumed that coarse-grained material strength dominates where bedding dips into a slope (favorable bedding) while fine-grained
material strength dominates where bedding dips out of a slope (adverse bedding). The
gеologic material strength map was modified by assigning the lower, fine-grained shear
strength values to areas where potential adverse bedding conditions were identified. The
favorable and adverse bedding shear strength parameters are included in Tables 2.1.

Existing Landslides

As discussed later in this report, the criteria for landslide zone mapping state that all
existing landslides that are mapped as definite or probable are automatically included in
the landslide zone of required investigation. Therefore, an evaluation of shear strength
parameters for existing landslides is not necessary for the preparation of the zone map.
However, in the interest of completeness for the material strength map, to provide
relevant material strength information to project plan reviewers, and to allow for future
revisions of our zone mapping procedures, we have collected and compiled shear strength
data considered representative of existing landslides within the quadrangle.

The strength characteristics of existing landslides (Qls) must be based on tests of the
materials along the landslide slip surface. Ideally, shear tests of slip surfaces formed in
each mapped geologic unit would be used. However, this amount of information is rarely
available, and for the preparation of the earthquake-induced landslide zone map it has
been assumed that all landslides within the quadrangle have the same slip surface
strength parameters. We collect and use primarily “residual” strength parameters from
laboratory tests of slip surface materials tested in direct shear or ring shear test
equipment. Back-calculated strength parameters, if the calculations appear to have been
performed appropriately, have also been used.

Within the Oakland East Quadrangle 11 shear tests of landslide slip surface materials
were located and the results are summarized in Table 2.1.

TABLE 2.2. Summary of Shear Strength Groups for the Oakland East Quadrangle.

**PART II**

**EARTHQUAKE-INDUCED LANDSLIDE HAZARD POTENTIAL**

**Design Strong-Motion Record**

To evaluate earthquake-induced landslide hazard potential in the study area, a method of dynamic slope stability analysis developed by Newmark (1965) was used. The Newmark method analyzes dynamic slope stability by calculating the cumulative down-slope displacement for a given earthquake strong-motion time history. As implemented for the preparation of earthquake-induced landslide zones, the Newmark method necessitates the selection of a design earthquake strong-motion record to provide the “ground shaking opportunity.”

Because the active Hayward Fault traverses diagonally through the Oakland East Quadrangle, the selection of a strong motion record was based on the desire to simulate a large earthquake on the Hayward Fault. The Hayward Fault is a right-lateral strike-slip fault with a total length of approximately 86 kilometers, and an estimated maximum moment magnitude of 7.1 (Petersen and others, 1996). The hilly areas of the quadrangle range from zero to about 5 kilometers from the seismic source. Strong-motion records considered in the selection include: the CGS Strong Motion Instrumentation Program (SMIP) Corralitos record from the 1989 Loma Prieta earthquake; the Southern California Edison (SCE) Lucerne record from the 1992 Landers earthquake; and the Japan Meteorological Agency (JMA) Kobe City record from the 1995 Hyogoken-Nambu
(Kobe) earthquake. The significant parameters for each of these earthquakes are listed below:

<table>
<thead>
<tr>
<th>Strong-Motion Record</th>
<th>Moment Magnitude</th>
<th>Source to Site Distance (km)</th>
<th>PGA (g)</th>
</tr>
</thead>
<tbody>
<tr>
<td>SMIP Corralitos</td>
<td>6.9</td>
<td>5.1</td>
<td>0.64</td>
</tr>
<tr>
<td>SCE Lucerne</td>

<td>1.1</td>
<td>0.80</td>
</tr>
<tr>
<td>JMA Kobe</td>
<td>6.9</td>
<td>0.6</td>
<td>0.82</td>
</tr>
</tbody>
</table>

The Corralitos record was eliminated because the fault motion was oblique, rather than purely strike-slip, and because of the relatively short rupture length. The Kobe record was eliminated because of uncertainties regarding the effects of topographic and basin-edge amplification at the recording site. Despite the slightly higher than expected magnitude, the Lucerne record from the 1992 Landers earthquake was used because it has many tectonic similarities to an earthquake on the Hayward Fault.

The selected strong-motion record was not scaled or otherwise modified prior to analysis.

**Displacement Calculation**

The design strong-motion record was used to develop a relationship between landslide displacement and yield acceleration ($a_y$), defined as the earthquake horizontal ground acceleration above which landslide displacements take place. This relationship was prepared by integrating the design strong-motion record twice for a given acceleration value to find the corresponding displacement, and the process was repeated for a range of acceleration values (Jibson, 1993). The resulting curve in Figure 2.1 represents the full spectrum of displacements that can be expected for the design strong-motion record. This curve provides the required link between anticipated earthquake shaking and estimates of displacement for different combinations of geologic materials and slope gradient, as described in the Slope Stability Analysis section below.

The amount of displacement predicted by the Newmark analysis provides an indication of the relative amount of damage that could be caused by earthquake-induced landsliding. Displacements of 30, 15 and 5 cm were used as criteria for rating levels of earthquake-induced landslide hazard potential based on the work of Youd (1980), Wilson and Keefer (1983), and a CGS pilot study for earthquake-induced landslides (McCrink and Real, 1996; McCrink, 2001). Applied to the curve in Figure 2.1, these displacements correspond to yield accelerations of 0.14, 0.18 and 0.24g. Because these yield acceleration values are derived from the design strong-motion record, they represent the ground shaking opportunity thresholds that are significant in the Oakland East Quadrangle.
Slope Stability Analysis

A slope stability analysis was performed for each geologic material strength group at slope increments of 1 degree. An infinite-slope failure model under unsaturated slope conditions was assumed. A factor of safety (FS) was calculated first, followed by the calculation of yield acceleration from Newmark’s equation:

\[ a_y = (FS - 1)g \sin \alpha \]

where FS is the Factor of Safety, g is the acceleration due to gravity, and \( \alpha \) is the direction of movement of the slide mass, in degrees measured from the horizontal, when displacement is initiated (Newmark, 1965). For an infinite slope failure \( \alpha \) is the same as the slope angle.
The yield accelerations resulting from Newmark’s equations represent the susceptibility to earthquake-induced failure of each geologic material strength group for a range of slope gradients. Based on the relationship between yield acceleration and Newmark displacement shown in Figure 2.1, hazard potentials were assigned as follows:

1. If the calculated yield acceleration was less than 0.14 g, Newmark displacement greater than 30 cm is indicated, and a HIGH hazard potential was assigned.

2. If the calculated yield acceleration fell between 0.14 g and 0.18 g, Newmark displacement between 15 cm and 30 cm is indicated, and a MODERATE hazard potential was assigned.

3. If the calculated yield acceleration fell between 0.18 g and 0.24 g, Newmark displacement between 5 cm and 15 cm is indicated, and a LOW hazard potential was assigned.

4. If the calculated yield acceleration was greater than 0.24 g, Newmark displacement of less than 5 cm is indicated, and a VERY LOW potential was assigned.

Table 2.3 summarizes the results of the stability analyses. The earthquake-induced landslide hazard potential map was prepared by combining the geologic material-strength map and the slope map according to this table.

Table 2.3. Hazard Potential Matrix for Earthquake-Induced Landslides in the Oakland East Quadrangle. Values in the table show the range of slope gradient (expressed as percent slope) corresponding to calculated Newmark displacement ranges from the design earthquake for each material strength group.
EARTHQUAKE-INDUCED LANDSLIDE HAZARD ZONE

Criteria for Zoning

Earthquake-induced landslide zones were delineated using criteria adopted by the California State Mining and Geology Board (DOC, 2000). Under these criteria, earthquake-induced landslide hazard zones are defined as areas that meet one or both of the following conditions:

1. Areas that have been identified as having experienced landslide movement in the past, including all mappable landslide deposits and source areas as well as any landslide that is known to have been triggered by historic earthquake activity.

2. Areas where the geologic and geotechnical data and analyses indicate that the earth materials may be susceptible to earthquake-induced slope failure.

These conditions are discussed in further detail in the following sections.

Existing Landslides

Existing landslides typically consist of disrupted soils and rock materials that are generally weaker than adjacent undisturbed rock and soil materials. Previous studies indicate that existing landslides can be reactivated by earthquake movements (Keefer, 1984). Earthquake-triggered movement of existing landslides is most pronounced in steep head scarp areas and at the toe of existing landslide deposits. Although reactivation of deep-seated landslide deposits is less common (Keefer, 1984), a significant number of deep-seated landslide movements have occurred during, or soon after, several recent earthquakes. Based on these observations, all existing landslides with a definite or probable confidence rating are included within the earthquake-induced landslide hazard zone.

Geologic and Geotechnical Analysis

Based on the conclusions of a pilot study performed by CGS (McCrink and Real, 1996; McCrink, 2001), it has been concluded that earthquake-induced landslide hazard zones should encompass all areas that have a High, Moderate or Low level of hazard potential (see Table 2.3). This would include all areas where the analyses indicate earthquake displacements of 5 centimeters or greater. Areas with a Very Low hazard potential, indicating less than 5 centimeters displacement, are excluded from the zone.

As summarized in Table 2.3, all areas characterized by the following geologic strength group and slope gradient conditions are included in the earthquake-induced landslide hazard zone:

1. Geologic Strength Group 5, consisting of all definite and probable landslide areas, is always included in the earthquake-induced landslide zone regardless of slope.

2. Geologic Strength Group 4 is included for all slopes steeper than 18 percent.
3. Geologic Strength Group 3 is included for all slopes steeper than 27 percent.
4. Geologic Strength Group 2 is included for all slopes steeper than 38 percent.
5. Geologic Strength Group 1 is included for all slopes steeper than 59 percent.

This results in approximately 20 percent of the Alameda County land area in the Oakland East Quadrangle lying within the earthquake-induced landslide hazard zone.

ACKNOWLEDGMENTS

The authors would like to thank the following individuals and organizations for their assistance in obtaining the data necessary to complete this project. At the City of Berkeley Jay Wilson and Glenn Carlsson greatly facilitated the collection of shear strength information. Alan Kropp of Alan Kropp Associates generously allowed access to his archive of consultant report files and collection of historic landslide information. Paul Lai at Berlogar Geotechnical Consultants allowed access to his firm’s geotechnical reports. Data collection for the earlier Oakland zone map, which this study used extensively, was facilitated by Joan Curtis and Mario Millan from the City of Oakland; Vern Phillips and Chester Nakahora from the City of Piedmont; Peter Dilks and Gary Moore from Alameda County; Herb Lotter from the City of Berkeley; Jeff Gee, Ron Gaul, and Nico Sanchez from the University of California at Berkeley; Fred Angliss from the Lawrence Berkeley Laboratory; and, Mark Caruso and Ken Ferrone from Harza Engineering Company. The selection of a representative strong-motion seismic record was greatly facilitated by discussions with Charles Real, Mark Petersen, Chris Cramer and Paul Summerville, and the displacement calculations for the considered records were carried out by Jacob Summerhayes. At CGS, Terilee McGuire, Lee Wallinder and Bob Moscovitz provided GIS support. Anne Rosinski and Kevin Clahan assisted in the shear test data collection. Barbara Wanish and Ross Martin prepared the final landslide hazard zone maps and the graphic displays for this report.

SECTION 3
GROUND SHAKING EVALUATION REPORT

Potential Ground Shaking in the
Oakland East 7.5-Minute Quadrangle,
Alameda County, California

By

PURPOSE

The Seismic Hazards Mapping Act (the Act) of 1990 (Public Resources Code, Chapter 7.8, Division 2) directs the California Department of Conservation (DOC), Division of Mines and Geology (DMG) [now called California Geological Survey (CGS)] to delineate Seismic Hazard Zones. The purpose of the Act is to reduce the threat to public health and safety and to minimize the loss of life and property by identifying and mitigating seismic hazards. Cities, counties, and state agencies are directed to use the Seismic Hazard Zone Maps in their land-use planning and permitting processes. The Act requires that site-specific geotechnical investigations be performed prior to permitting most urban development projects within the hazard zones. Evaluation and mitigation of seismic hazards are to be conducted under guidelines established by the California State Mining and Geology Board (DOC, 1997). The text of this report is on the Internet at http://gmw.consrv.ca.gov/shmp/webdocs/sp117.pdf

This section of the evaluation report summarizes the ground motions used to evaluate liquefaction and earthquake-induced landslide potential for zoning purposes. Included are ground motion and related maps, a brief overview on how these maps were prepared, precautionary notes concerning their use, and related references. The maps provided
herein are presented at a scale of approximately 1:150,000 (scale bar provided on maps), and show the full 7.5-minute quadrangle and portions of the adjacent eight quadrangles. They can be used to assist in the specification of earthquake loading conditions for the analysis of ground failure according to the “Simple Prescribed Parameter Value” method (SPPV) described in the site investigation guidelines (California Department of Conservation, 1997). Alternatively, they can be used as a basis for comparing levels of ground motion determined by other methods with the statewide standard.

This section and Sections 1 and 2 (addressing liquefaction and earthquake-induced landslide hazards) constitute a report series that summarizes development of seismic hazard zone maps in the state. Additional information on seismic hazard zone mapping in California can be accessed on the California Geological Survey's Internet page: http://www.conservation.ca.gov/CGS/index.htm

**EARTHQUAKE HAZARD MODEL**

The estimated ground shaking is derived from the statewide probabilistic seismic hazard evaluation released cooperatively by the California Department of Conservation, Division of Mines and Geology [California Geological Survey], and the U.S. Geological Survey (Petersen and others, 1996). That report documents an extensive 3-year effort to obtain consensus within the scientific community regarding fault parameters that characterize the seismic hazard in California. Fault sources included in the model were evaluated for long-term slip rate, maximum earthquake magnitude, and rupture geometry. These fault parameters, along with historical seismicity, were used to estimate return times of moderate to large earthquakes that contribute to the hazard.

The ground shaking levels are estimated for each of the sources included in the seismic source model using attenuation relations that relate earthquake shaking with magnitude, distance from the earthquake, and type of fault rupture (strike-slip, reverse, normal, or subduction). The published hazard evaluation of Petersen and others (1996) only considers uniform firm-rock site conditions. In this report, however, we extend the hazard analysis to include the hazard of exceeding peak horizontal ground acceleration (PGA) at 10 percent probability of exceedance in 50 years on spatially uniform conditions of rock, soft rock, and alluvium. These soil and rock conditions approximately correspond to site categories defined in Chapter 16 of the Uniform Building Code (ICBO, 1997), which are commonly found in California. We use the attenuation relations of Boore and others (1997), Campbell (1997), Sadigh and others (1997), and Youngs and others (1997) to calculate the ground motions.

The seismic hazard maps for ground shaking are produced by calculating the hazard at sites separated by about 5 km. Figures 3.1 through 3.3 show the hazard for PGA at 10 percent probability of exceedance in 50 years assuming the entire map area is firm rock, soft rock, or alluvial site conditions respectively. The sites where the hazard is calculated are represented as dots and ground motion contours as shaded regions. The quadrangle of interest is outlined by bold lines and centered on the map. Portions of the eight

adjacent quadrangles are also shown so that the trends in the ground motion may be more apparent. We recommend estimating ground motion values by selecting the map that matches the actual site conditions, and interpolating from the calculated values of PGA rather than the contours, since the points are more accurate.

APPLICATIONS FOR LIQUEFACTION AND LANDSLIDE HAZARD ASSESSMENTS

Deaggregation of the seismic hazard identifies the contribution of each of the earthquakes (various magnitudes and distances) in the model to the ground motion hazard for a particular exposure period (see Cramer and Petersen, 1996). The map in Figure 3.4 identifies the magnitude and the distance (value in parentheses) of the earthquake that contributes most to the hazard at 10 percent probability of exceedance in 50 years on alluvial site conditions (predominant earthquake). This information gives a rationale for selecting a seismic record or ground motion level in evaluating ground failure. However, it is important to keep in mind that more than one earthquake may contribute significantly to the hazard at a site, and those events can have markedly different magnitudes and distances. For liquefaction hazard the predominant earthquake magnitude from Figure 3.4 and PGA from Figure 3.3 (alluvium conditions) can be used with the Youd and Idriss (1997) approach to estimate cyclic stress ratio demand. For landslide hazard the predominant earthquake magnitude and distance can be used to select a seismic record that is consistent with the hazard for calculating the Newmark displacement (Wilson and Keefer, 1983). When selecting the predominant earthquake magnitude and distance, it is advisable to consider the range of values in the vicinity of the site and perform the ground failure analysis accordingly. This would yield a range in ground failure hazard from which recommendations appropriate to the specific project can be made. Grid values for predominant earthquake magnitude and distance should not be interpolated at the site location, because these parameters are not continuous functions.

A preferred method of using the probabilistic seismic hazard model and the “simplified Seed-Idriss method” of assessing liquefaction hazard is to apply magnitude scaling probabilistically while calculating peak ground acceleration for alluvium. The result is a “magnitude-weighted” ground motion (liquefaction opportunity) map that can be used directly in the calculation of the cyclic stress ratio threshold for liquefaction and for estimating the factor of safety against liquefaction (Youd and Idriss, 1997). This can provide a better estimate of liquefaction hazard than use of predominate magnitude described above, because all magnitudes contributing to the estimate are used to weight the probabilistic calculation of peak ground acceleration (Real and others, 2000). Thus, large distant earthquakes that occur less frequently but contribute more to the liquefaction hazard are appropriately accounted for.

Figure 3.5 shows the magnitude-weighted alluvial PGA based on Idriss’ weighting function (Youd and Idriss, 1997). It is important to note that the values obtained from this map are pseudo-accelerations and should be used in the formula for factor of safety without any magnitude-scaling (a factor of 1) applied.

USE AND LIMITATIONS

The statewide map of seismic hazard has been developed using regional information and is not appropriate for site specific structural design applications. Use of the ground motion maps prepared at larger scale is limited to estimating earthquake loading conditions for preliminary assessment of ground failure at a specific location. We recommend consideration of site-specific analyses before deciding on the sole use of these maps for several reasons.

1. The seismogenic sources used to generate the peak ground accelerations were digitized from the 1:750,000-scale fault activity map of Jennings (1994). Uncertainties in fault location are estimated to be about 1 to 2 kilometers (Petersen and others, 1996). Therefore, differences in the location of calculated hazard values may also differ by a similar amount. At a specific location, however, the log-linear attenuation of ground motion with distance renders hazard estimates less sensitive to uncertainties in source location.

2. The hazard was calculated on a grid at sites separated by about 5 km (0.05 degrees). Therefore, the calculated hazard may be located a couple kilometers away from the site. We have provided shaded contours on the maps to indicate regional trends of the hazard model. However, the contours only show regional trends that may not be apparent from points on a single map. Differences of up to 2 km have been observed between contours and individual ground acceleration values. We recommend that the user interpolate PGA between the grid point values rather than simply using the shaded contours.

3. Uncertainties in the hazard values have been estimated to be about +/- 50 percent of the ground motion value at two standard deviations (Cramer and others, 1996).

4. Not all active faults in California are included in this model. For example, faults that do not have documented slip rates are not included in the source model. Scientific research may identify active faults that have not been previously recognized. Therefore, future versions of the hazard model may include other faults and omit faults that are currently considered.

5. A map of the predominant earthquake magnitude and distance is provided from the deaggregation of the probabilistic seismic hazard model. However, it is important to recognize that a site may have more than one earthquake that contributes significantly to the hazard. Therefore, in some cases earthquakes other than the predominant earthquake should also be considered.

Because of its simplicity, it is likely that the SPPV method (DOC, 1997) will be widely used to estimate earthquake shaking loading conditions for the evaluation of ground failure hazards. It should be kept in mind that ground motions at a given distance from an earthquake will vary depending on site-specific characteristics such as geology, soil properties, and topography, which may not have been adequately accounted for in the regional hazard analysis. Although this variance is represented to some degree by the
recorded ground motions that form the basis of the hazard model used to produce Figures 3.1, 3.2, and 3.3, extreme deviations can occur. More sophisticated methods that take into account other factors that may be present at the site (site amplification, basin effects, near source effects, etc.) should be employed as warranted. The decision to use the SPPV method with ground motions derived from Figures 3.1, 3.2, or 3.3 should be based on careful consideration of the above limitations, the geotechnical and seismological aspects of the project setting, and the “importance” or sensitivity of the proposed building with regard to occupant safety.
